Abstract

This paper introduces a tree-based model that combines aspects of classification and regression trees (CART) and smooth transition regression (STR). The model is called the STR-tree. The main idea relies on specifying a parametric nonlinear model through a tree-growing procedure. The resulting model can be analyzed as a smooth transition regression with multiple regimes. Decisions about splits are entirely based on a sequence of Lagrange multiplier (LM) tests of hypotheses. An alternative specification strategy based on a 10-fold cross-validation is also discussed and a Monte Carlo experiment is carried out to evaluate the performance of the proposed methodology in comparison with standard techniques. The STR-tree model outperforms CART when the correct selection of the architecture of simulated trees is discussed. Furthermore, the LM test seems to be a promising alternative to 10-fold cross-validation. Function approximation is also analyzed. When put into proof with real and simulated data sets, the STR-tree model has a superior predictive ability than CART.

Keywords: Regression-trees; CART; Smooth transition; Nonlinear regression; Modeling cycle 

1. Introduction

In recent years much attention has been devoted to nonlinear modeling. Techniques such as artificial neural networks, nonparametric regression and recursive partitioning methods are frequently used to approximate unknown functional forms (Murthy, 1998; Hastie et al., 2001). This paper considers a nonlinear regression model that combines aspects of two well-known methodologies: classification and regression trees (CART) discussed in Breiman et al. (1984) and the smooth transition regression (STR) presented in Granger and Teräsvirta (1993). The proposed model is called the STR-tree. The CART methodology represents a unification of all tree-based classification and prediction methods that have been developed since Morgan and Sonquist (1963). It transformed the regression tree models in an important nonparametric alternative to the classical methods of regression. Since then, the attractiveness of this methodology has motivated many authors to create hybrid modeling strategies that merge tree techniques with known statistical methods. See, for example, Segal (1992) in a context of longitudinal data analysis, Ahn (1996) for survival analysis, and Cooper (1998) for time series analysis. Other approaches can be found in Ciampi (1991), Crowley and Blanc (1993), and Denison et al. (1998).

Allowing smooth splits on the tree nodes instead of sharp ones, we associate each tree architecture with a smooth transition regression model and thus it turns possible to formulate a splitting criteria that are entirely based on statistical tests of hypotheses. The Lagrange multiplier (LM) test in the context presented by Luukkonen et al. (1988) is adapted for deciding if a node should be split or not. The tree growing procedure is used as a tool for specifying a parametric model that can be analyzed either as STR model or as a fuzzy regression (Jajuga, 1986). In the former case, we can obtain confidence intervals for the parameters’ estimates in the tree leaves and predicted values. In the regression-tree literature, the replacement of sharp splits by soft (of smooth) thresholds is not a new idea; see Chang and Pavlidis (1977), Jang (1994), Yuan and Shaw (1995), Janickow (1998), Suárez and Lutsko (1999), and Olaru and Wehenkel (2003). However, we contribute to regression-tree literature by proposing a coherent model building strategy fully based on statistical arguments. Our proposal is simple, easily implemented, and is not computer intensive. Furthermore, decisions based on statistical inference also lessen the importance of post-pruning techniques to reduce the model complexity and circumvent identification problems common in nonlinear regressions; see Medeiros et al. (2006) for a related discussion. An alternative specification strategy based on a 10-fold cross-validation is considered. An extension of the basic model to allow for the inclusion of categorical variables is discussed. A detailed Monte Carlo experiment is carried out to evaluate the performance of the proposed methodology in comparison with standard techniques. The STR-tree model outperforms CART when the correct selection of the architecture of simulated trees is considered. Even when the true model is a regression-tree with sharp splits, the model building strategy proposed here selects the correct architecture in almost 100% of the cases. Furthermore, the LM test is less computer-intensive than 10-fold cross-validation. Finally, the simulation study also shows that the STR-tree model is a promising alternative when out-of-sample prediction of unknown nonlinear functions is considered. When put into proof with real data sets, the STR-tree model has a superior predictive ability than CART. Model averaging is discussed and the main result is that the combination of the STR-tree model with the multivariate adaptive regression splines (MARS) of Friedman (1991) is a viable alternative to nonlinear prediction. A Matlab code for carrying out the modeling cycle exists and can be obtained from the authors.

The paper is divided as follows. In Section 2, we briefly introduce some important regression tree concepts and introduce the main notation. Section 3 describes the proposed model. Section 4 discusses the model building strategy and parameter estimation. The use of categorical data is considered in Section 5. A Monte Carlo Experiment is conducted in Section 6. Examples with six data sets are presented in Section 7. Finally, Section 8 concludes. A technical appendix provides the proofs of the theorems.

2. Regression trees

A regression tree is a nonparametric model which looks for the best local prediction of a continuous response through the recursive partitioning of the space of the predictor variables. Usually, regression trees are estimated by a greedy recursive partitioning algorithm; see Breiman et al. (1984). The fitted model is displayed in a graph which has the format of a binary decision tree with 

2.1. Mathematical formulation

Let \( \mathbf{x}_t = (x_{t1}, \ldots, x_{tm})' \in \mathbb{X} \subseteq \mathbb{R}^m \) be a vector which contains \( m \) explanatory variables for a continuous univariate response \( y_t \in \mathbb{R} \). The relationship between \( y_t \) and \( \mathbf{x}_t \) follows the regression model:

\[
y_t = f(\mathbf{x}_t) + \epsilon_t,
\]

where the functional form \( f(\cdot) \) is unknown and there are no assumptions about the distribution of the random term \( \epsilon_t \). Following Lewis and Stevens (1991), a regression tree model with \( K \) leaves is a recursive partitioning model that approximates \( f(\cdot) \) by a general nonlinear function \( H(\mathbf{x}_t; \psi) \) of \( \mathbf{x}_t \), indexed by the vector of parameters \( \psi \in \mathbb{R}^r \); \( r \) is the total number of parameters. Frequently, \( H(\cdot) \) is a piecewise constant function defined by \( K \) subregions \( k_i(\theta_i) \), \( i = 1, \ldots, K \), of some domain \( \mathbb{X} \subseteq \mathbb{R}^m \). Each region is determined by the parameter vector \( \theta_i, i = 1, \ldots, K \), such that

\[
f(\mathbf{x}_t) \approx \sum_{i=1}^{K} \beta_i I_i(\mathbf{x}_t; \theta_i),
\]
where
\[ I_i(x; \theta_i) = \begin{cases} 1 & \text{if } x_i \in k_i(\theta_i), \\ 0 & \text{otherwise}, \end{cases} \]
(3)

and \( \psi = (\beta_1, \ldots, \beta_K, \theta'_1, \ldots, \theta'_K)' \). Conditionally to the knowledge of the subregions, the relationship between \( y_t \) and \( x_t \) in (1) is approximated by a linear regression on a set of \( K \) dummy variables.

The most important reference in regression tree models is the CART approach discussed in Breiman et al. (1984). In this context, it is usual to define the subregions \( k_i, i = 1, \ldots, K, \) in (2) by hyperplanes that are orthogonal to the axis of the predictor variables. For example, consider a simple tree structure with \( K = 2 \) leaves and depth \( d = 1 \). The unknown function \( f(x_t) \) in (1) may be approximated by a constant model in each leaf, written as
\[ y_t = \beta'_1 I(x_t; s_0, c_0) + \beta'_2[1 - I(x_t; s_0, c_0)] + e_t, \]
(4)

where
\[ I(x_t; s_0, c_0) = \begin{cases} 1 & \text{if } x_{s0t} \leq c_0, \\ 0 & \text{otherwise}, \end{cases} \]
(5)
s0 \( \in \mathbb{S} = \{1, 2, \ldots, m\} \), and \( x_{s0t} \in x_t \).

3. Tree-structured smooth transition regression (STR-tree)

The main idea of the STR-tree model is to take advantage of the CART structure, but also to introduce elements which make it feasible to use standard inferential procedures. Whenever possible, we intend to keep the interpretability of the tree-based models. The highly discontinuous functional form of the model fitted by the CART and the strategy to decrease the sum of squared errors by splitting the sample recursively, pose a problem to test the significance of the model and to make classical inference. The idea here is the same used in Suárez and Lutsko (1989): the substitution of sharp splits in the CART model by smooth splits. Consider the simplest tree with two terminal nodes generated as in
When the slope parameter approaches zero, it leads to the fuzziest situation in which there is no gain in splitting the data. If we replace the indicator function \( \mathbb{I}(\cdot) \) in (4) by a logistic function defined as

\[
G(x_t; s_0, \gamma_0, c_0) = \frac{1}{1 + e^{-\gamma_0(x_t - c_0)}},
\]

we obtain \( y_t = \beta_1 G(x_t; s_0, \gamma_0, c_0) + \beta_2 [1 - G(x_t; s_0, \gamma_0, c_0)] + e_t \), where now we have the additional parameter \( \gamma_0 \), called the slope parameter, which controls the smoothness of the logistic function. This change causes an important difference from the CART approach: splitting the root node will not separate two subsets of observations but it will create two fuzzy sets (Zadeh, 1965) where all observations will belong to, but with a different degree of membership. When the slope parameter approaches zero, it leads to the fuzziest situation in which there is no gain in splitting the data. The parameter \( c_0 \) is called the location parameter. When the transition is very smooth the model looses the standard tree interpretability. However, the STR-tree model can be seen as a fuzzy regression model or a model where we associate a probability of being in each regime.

As the CART node partition is nested in the smooth transition approach as a special case when the slope parameter approaches infinity, we argue that the STR-tree model inherits all the function approximation properties of the regression-trees with sharp splits.

Replacing the sharp splits by smooth ones has some advantages. Firstly, standard inferential theory can be used to test hypothesis about the location of the splits and to construct confidence intervals to the predictions. Moreover, as shown in the simulations in Section 6, cross-validation is inefficient in specifying correct-sized trees and is computationally intensive. Finally, smoothing between adjacent nodes can reduce bias and variance in the predictions, specially near the node boundaries. Finally, it is possible to interpret the regression tree approach as a particular case of the STR models discussed in Chan and Tong (1986) and Granger and Teräsvirta (1993).

4. Model building

The architecture of tree-based models is usually determined from the data. Popular methods for doing that are based on cross-validation or information criteria. Applying an information criterion (IC) to decide whether or not another given node should be split requires estimation of a more complex model (with one more split). In this situation the larger model is not identified and its parameters cannot be estimated consistently. This is likely to cause numerical problems in maximum likelihood estimation. Besides, even when convergence is achieved, lack of identification causes a severe problem in interpreting the IC. The tree model with more terminal nodes (splits) is nested in the model with less terminal nodes. A typical IC comparison of the two models is then equivalent to a likelihood ratio test, see, for example, Teräsvirta and Mellin (1986) for discussion. The choice of the IC determines the (asymptotic) significance level of the test. But then, when the larger model is not identified under the null hypothesis, the likelihood ratio statistic does not have its customary asymptotic \( \chi^2 \) distribution when the null holds. For more discussion of the general situation of a model only being identified under the alternative hypothesis, see, for example, Davies (1977, 1987) and Hansen (1996).

Here we adopt a different strategy following the modeling cycle described in Teräsvirta (1994), Medeiros and Veiga (2005), and Medeiros et al. (2006). The “architecture” of the model has to be determined from the data and we call this stage specification of the model, which involves two decisions: the selection of the node to be split and the index of the splitting variable. The specification stage will be carried out by a sequence of LM tests following the ideas originally presented in Luukkonen et al. (1988). An alternative approach based on 10-fold cross-validation is also possible; however the computational burden involved is dramatically high. The specification stage also requires estimation of the parameters of the model. What follows thereafter is evaluation of the final estimated model. Tree models are usually evaluated by their out-of-sample performance (predictive ability). In this paper we follow the literature and evaluate the STR-tree model in the same way. The construction of misspecification tests for the STR-tree model in the same spirit of Eitrheim and Teräsvirta (1996) is also possible, but this topic is beyond the scope of the paper.

Following the “specific-to-general” principle, we start the cycle from the root node (depth 0) and the general steps are:

1. Specification of the model by selecting in the depth \( d \), using the LM test, a node to be split (if not in the root node) and a splitting variable.
2. Parameter estimation.
(3) Evaluation of the estimated model by checking if it is necessary to: (a) change the node to be split; (b) change the splitting variable; and (c) remove the split.
(4) Use the final tree model for prediction or descriptive purposes.

The modeling cycle begins from the root node (depth 0) by testing the null hypothesis of a global constant model against a STR-tree model with only two terminal nodes.

4.1. Parameter estimation

Consider a full-grown STR-tree model with depth \( d, K = 2^d \) terminal nodes (leaves), and \( N = \sum_{i=1}^{d} 2^i \) parent nodes, defined as

\[
y_t = H(x_t; \psi) + \varepsilon_t = \sum_{k=1}^{K} \beta_{K+k-2} B_k(x_t; \theta_k) + \varepsilon_t,
\]

where \( H(x_t; \psi) = \sum_{k=1}^{K} \beta_{K+k-2} B_k(x_t; \theta_k) \) and \( B_k(x_t; \theta_k), k=1, \ldots, K, \) is defined by products of the logistic function. The parameter vector \( \psi = (\beta_{K-1}, \beta_{2K-2}, \theta_1^T, \ldots, \theta_K^T) \) has \( r = K + 2N \) elements. As an example, consider a STR-tree model with depth \( d = 2, K = 4, N = 3, \) and functions \( B_k(x_t; \theta_k), k=1, \ldots, K, \) in (7) written as

\[
B_1(x_t; \theta_1) = G(x_t; s_0, \gamma_0, c_0)G(x_t; s_1, \gamma_1, c_1),
\]
\[
B_2(x_t; \theta_2) = G(x_t; s_0, \gamma_0, c_0)[1 - G(x_t; s_1, \gamma_1, c_1)],
\]
\[
B_3(x_t; \theta_3) = [1 - G(x_t; s_0, \gamma_0, c_0)]G(x_t; s_2, \gamma_2, c_2)
\]
and
\[
B_4(x_t; \theta_4) = [1 - G(x_t; s_0, \gamma_0, c_0)][1 - G(x_t; s_2, \gamma_2, c_2)].
\]

The total number of parameters to be estimated is 10 and there are three splitting variables to be selected. It is important to stress that all tree architectures can be seen as a restricted version of a full grown tree, which is used here just to make the presentation clearer.

4.1.1. Main assumptions

At this point we have to make the following set of assumptions.

**Assumption 1.** The sequence \( \{x_t\}_{t=1}^{T} \) is formed by independent and identically distributed (IID) random vectors and have a common joint distribution \( \mathcal{G} \) on \( \Lambda, \) a measurable Euclidean space, with measurable Radon-Nikodým density.

**Assumption 2.** The sequence \( \{\varepsilon_t\}_{t=1}^{T} \) is formed by independent and normally distributed (NID) random variables with zero mean and variance \( \sigma^2 < \infty, \) that is \( \varepsilon_t \sim NID(0, \sigma^2). \)

**Assumption 3.** The \( r \times 1 \) true parameter vector \( \psi^* \) is an interior point of the compact parameter space \( \Psi \) which is a subspace of \( \mathbb{R}^r, \) the \( r \)-dimensional Euclidean space.

**Assumption 4.** The parameters \( \gamma_i > 0, i = 1, \ldots, N, \) where \( N \) is the number of parent nodes. Furthermore, if for two adjacent parent nodes at positions \( 2j + 1 \) and \( 2j + 2, x_{s_{2j+1}t} = x_{s_{2j+2}t}, \) then \( c_{s_{2j+1}} < c_{s_{2j+2}}. \)

Assumption 1 states that we are working with IID data such as cross-sectional or a set of time-series with IID observations. Although Assumption 2 may seem a little restrictive, model (7) is still very flexible. Furthermore, Assumption 2 allows us to work in a maximum likelihood framework that will be equivalent to nonlinear least-squares. In the case of non-Gaussian errors, Assumption 2 may be substituted by some moment conditions and a quasi-maximum likelihood framework should be used instead. The main difference will be related to the computation of the covariance matrix of the parameter estimates. In addition, a robust version of the tests presented latter can be constructed in the same
spirit of Wooldridge (1991) and Medeiros et al. (2006). Assumption 3 is standard and Assumption 4 guarantees that the STR-tree model is identifiable.

As discussed previously, we estimate the parameters of our STR-tree model by maximum likelihood (ML). The use of maximum likelihood makes it possible to obtain an idea of the uncertainty in the parameter estimates through (asymptotic) standard deviation estimates. The STR-tree model is similar to many linear or nonlinear models in that the information matrix of the log-likelihood function is block diagonal in such a way that we can concentrate the likelihood and first estimate the parameters of the conditional mean. Conditional maximum likelihood is thus equivalent to nonlinear least squares (NLS).

The nonlinear least squares estimator (NLSE) of the parameters equals

$$\hat{\psi} = \arg\min_{\psi \in \Psi} \frac{1}{T} Q_T(\psi) = \arg\min_{\psi \in \Psi} \frac{1}{T} \sum_{t=1}^{T} q_t(\psi) = \arg\min_{\psi \in \Psi} \frac{1}{T} \sum_{t=1}^{T} e_t^2. $$

(8)

4.1.2. Existence

The proof of existence of the NLSE is based on Lemma 2 of Jennrich (1969), which establishes that under certain conditions of continuity and measurability on the mean square error (MSE) function, the NLSE as in (8) exists. Theorem 1 states the necessary conditions for the existence of the NLSE.

**Theorem 1.** The STR-tree model satisfies the following conditions and the NLSE exists:

1. For each $x_t \in \mathbb{X} \subseteq \mathbb{R}^m$, function $H_x(\psi) = H(x_t; \psi)$ is continuous in compact subset $\Psi$ of the Euclidean space.
2. For each $\psi \in \Psi \subseteq \mathbb{R}^r$, function $H_\psi(\mathbb{X}) = H(x_t; \psi)$ is measurable in space $\mathbb{X}$.
3. $\varepsilon_t \sim \text{IID}(0, \sigma^2)$.

4.1.3. Consistency

The consistency of the NLSE was proved in Jennrich (1969). We follow Amemiya (1983) and state the following theorem.

**Theorem 2.** Under the Assumptions 1–5 $\hat{\psi}$ is strong consistent for $\psi^*$, i.e., $\hat{\psi} \stackrel{\text{a.s.}}{\rightarrow} \psi^*$.

4.1.4. Asymptotic normality

Asymptotic normality of the NLSE was also carefully proved in Jennrich (1969). We follow his results and the developments in Amemiya (1983) and state the following theorem.

**Theorem 3.** Under the Assumptions 1–5

$$T^{1/2}(\hat{\psi} - \psi^*) \overset{d}{\rightarrow} N \left(0, -\lim_{T \to \infty} A(\psi^*)^{-1}\right),$$

(9)

where $A(\psi^*) = (1/\sigma^2) \nabla^2 Q_T(\psi^*) / \nabla \psi \nabla \psi'$.

**Remark 1.** The extension of the above theorems to the case of non-IID observations and to misspecified models is relatively straightforward. The results of White (1982, 1994), and Wooldridge (1994) can be applied.

4.1.5. Concentrated least-squares

Conditional on the knowledge of the parameters $\theta_k$ in (7), $k = 1, \ldots, K$, model (7) is just a linear regression and the vector of parameters $\beta = (\beta_{K-1}, \ldots, \beta_{2K-2})'$ can be estimated by ordinary least-squares (OLS) as

$$\hat{\beta} = [B(\theta)B(\theta)]^{-1}B(\theta)'y.$$
where \( y = (y_1, \ldots, y_T)' \), \( \theta = (\theta_1', \ldots, \theta_K')' \), and

\[
B(\theta) = \begin{pmatrix}
B_1(x_1; \theta_1) & \cdots & B_K(x_1; \theta_K) \\
\vdots & \ddots & \vdots \\
B_1(x_T; \theta_1) & \cdots & B_K(x_T; \theta_K)
\end{pmatrix}.
\]

The parameters \( \theta_k, k = 1, \ldots, K \), are estimated conditionally on \( \beta \) by applying the Levenberg–Marquardt algorithm which completes the \( i \)th iteration.

### 4.2. Splitting the nodes

We have a particular interest in the hypothesis concerning the significance of splitting the root node. If we re-parameterize the STR-tree model as

\[
y_t = \phi_0 + \lambda_0 G(x_t; s_0, \gamma_0, c_0) + \epsilon_t,
\]

where \( \phi_0 = \beta_2 \) and \( \lambda_0 = \beta_1 - \beta_2 \), we obtain a more parsimonious representation of the simplest STR-tree model. In order to test the significance of the first split, a convenient null hypothesis is \( H_0 : \gamma_0 = 0 \) against the alternative \( H_a : \gamma_0 > 0 \). An equivalent null hypothesis is \( H_0 : \lambda_0 = 0 \). However, under \( H_0 \), the nuisance parameters \( \lambda_0 \) and \( c_0 \) can assume different values without changing the likelihood function. This poses an identification problem whose solution was first discussed by Davies (1977).

We adopt as a solution for this problem the one proposed in Luukkonen et al. (1988), that is to approximate the function \( G(\cdot) \) by a third-order Taylor expansion around \( \gamma = 0 \). After some algebra we get

\[
y_t = x_0 + x_1 x_{s_0,t} + x_2 x_{s_0,t}^2 + x_3 x_{s_0,t}^3 + \epsilon_t,
\]

where \( x_i, i = 0, 1, 2, 3 \), is a parameter that is a function of \( \gamma_0, c_0, \phi_0 \), and \( \lambda_0, \epsilon_t = \hat{\epsilon}_t + \lambda_0 R(x_t; s_0, \gamma_0, c_0) \), and \( R(x_t; s_0, \gamma_0, c_0) \) is the remainder. Thus,

\[
H_0 : x_i = 0, \quad i = 1, 2, 3.
\]

Note that under \( H_0 \), the remainder of the Taylor expansion vanishes and \( \epsilon_t = \hat{\epsilon}_t \), so that the properties of the error process remain unchanged under the null and thus asymptotic inference can be used. Finally, one may also view (12) as resulting from a local approximation to the log-likelihood function, which for observation \( t \) takes the form

\[
l_t = -\frac{1}{2} \ln(2\pi) - \frac{1}{2} \ln \sigma^2 - \frac{1}{2\sigma^2} \left( y_t - x_0 - x_1 x_{s_0,t} - x_2 x_{s_0,t}^2 - x_3 x_{s_0,t}^3 \right)^2.
\]

At this point we make the following additional assumption.

**Assumption 5.** \( E| x_{s_0,t} |^\delta < \infty, \forall s_0 \in S, \) for some \( \delta > 6 \).

This enables us to state the following well-known result.

**Theorem 4.** Under \( H_0 : \gamma_0 = 0 \) and Assumptions 2–5, the LM type statistic

\[
LM = \frac{1}{\sigma^2} \sum_{t=1}^{T} \sum_{i=1}^{T} \hat{\epsilon}_t v_i' \left( \sum_{t=1}^{T} v_i h_i' \left( \sum_{t=1}^{T} h_i h_i' \right)^{-1} \sum_{t=1}^{T} h_i v_i' \right)^{-1} \sum_{t=1}^{T} v_i \hat{\epsilon}_t,
\]

where \( \hat{\epsilon}_t = y_t - \hat{\beta}_0 \) is the estimated residuals under the null, \( \hat{\sigma}^2 = (1/T) \sum_{t=1}^{T} \hat{\epsilon}_t^2, h_i = 1, \) and \( v_i = (x_{s_0,t}, x_{s_0,t}^2, x_{s_0,t}^3)' \), has an asymptotic \( \chi^2 \) distribution with 3 degrees of freedom.

**Remark 2.** Note that, under \( H_0 \), \( \hat{\beta}_0 = \frac{1}{T} \sum_{t=1}^{T} y_t \xrightarrow{p} \mathbb{E}(y_t) \).
Until this point, we have just interpreted the simplest tree model as a particular case of the STR model as in Granger and Teräsvirta (1993), and the testing strategy to split the root node corresponds to a linearity test in which the linear model in question is a global constant model. However, the key idea is to consider the basic testing procedure described above in a more complex framework. To give an example of a more complex model, consider that the null hypothesis (13) was rejected and a STR-tree model with two leaves was consistently estimated. A natural way, within the tree framework, of considering a hypothesis of misspecification is by formulating a new model that splits one between the two created nodes, say the left child node, leading to the following model

\[ y_t = H(x_t; \psi) + \epsilon_t \]

\[ = \{ \beta_2 G(x_t; s_1, \gamma_1, c_1) + \beta_4[1 - G(x_t; s_1, \gamma_1, c_1)]\} G(x_t; s_0, \gamma_0, c_0) + \beta_2[1 - G(x_t; s_0, \gamma_0, c_0)] + \epsilon_t. \]  

(16)

Therefore, rewriting (16) as

\[ y_t = [\phi_1 + \lambda_1 G(x_t; s_1, \gamma_1, c_1)] G(x_t; s_0, \gamma_0, c_0) + \beta_2[1 - G(x_t; s_0, \gamma_0, c_0)] + \epsilon_t, \]

(17)

where \( \phi_1 = \beta_2 \) and \( \lambda_1 = \beta_2 - \beta_4 \), a convenient null hypothesis is \( H_0 : \gamma_1 = 0 \).

However, under the null hypothesis, the model (17) cannot be consistently estimated because of the nuisance parameters \( \lambda_1 \) and \( c_1 \). For solving this identification problem, we proceed as before and approximate the function \( G(\cdot) \) by its third-order Taylor expansion around \( H_0 \). After some algebra we get

\[ y_t = \alpha_1 + \alpha_1 G(x_{s0l}; \gamma_0, c_0) + \alpha_2 G(x_{s0l}; \gamma_0, c_0)x_{s1t} + \alpha_3 G(x_{s0l}; \gamma_0, c_0)x_{s1t}^2 + \alpha_4 G(x_{s0l}; \gamma_0, c_0)x_{s1t}^3 + \epsilon_t, \]

(18)

where \( \epsilon_t = \epsilon_t + R(x_t; s_1, \gamma_1, c_1) ; \) \( R(x_t; s_1, \gamma_1, c_1) \) is the remainder. The decision for splitting the node corresponds to the rejection of the following null hypothesis:

\[ H_0 : \alpha_1 = 0, \quad i = 2, 3, 4. \]  

(19)

The test statistic is (15) with

\[ h_t = \left( 1, G(x_{s0l}; \gamma_0, c_0), \bar{\delta} G(x_{s0l}; \gamma_0, c_0), \bar{\delta} G(x_{s0l}; \gamma_0, c_0) \right) \]

and \( v_t = (G(x_{s0l}; \gamma_0, c_0)x_{s1t}, G(x_{s0l}; \gamma_0, c_0)x_{s1t}^2, G(x_{s0l}; \gamma_0, c_0)x_{s1t}^3)' \).

From the assumption of normality of the error term, the information matrix is block diagonal and thus we can assume that the error variance is fixed. The test can be carried out according to the following steps:

1. Estimate the STR-tree model under the null hypothesis \( H_0 \) and compute the residuals \( \hat{\epsilon}_t \). Compute the sum of the squared residuals \( SSR_0 = \sum_{t=1}^{T} \hat{\epsilon}_t^2 \).
2. Regress \( \hat{\epsilon}_t \) on \( h_t \) and \( v_t \). Compute the sum of squared residuals obtained from this regression (\( SSR_1 \)).
3. Compute the \( \chi^2 \) statistic

\[ LM_F = T \frac{SSR_0 - SSR_1}{SSR_0}, \]

(20)

or the \( F \) version of the test

\[ LM_F = \frac{(SSR_0 - SSR_1)/3}{SSR_1/(T - 7)}, \]

(21)

where \( T \) is the sample size. Under the null \( LM_F \) is asymptotically distributed as a \( \chi^2 \) distribution with 3 degrees of freedom and \( LM_F \) has an asymptotic \( F \) distribution with 3 and \( T - 7 \) degrees of freedom.

Hereafter, the idea is to carry out a sequence of LM-type tests to grow the tree model in the same format as the one presented above and the general form of the test statistic when testing a model with \( j \) nodes against an alternative with
$j + 1$ nodes is given by:

$$LM = \frac{(SSR_0 - SSR_1)/3}{SSR_1/[T - (p + 3)]},$$

(22)

where $p$ is the total number of elements of the vector $h_t$.

4.2.1. Modeling cycle from the root node (depth 0)

The decision to split the root node is based on the following steps.

1. For each explanatory variable, apply the LM-type test described above and select the variable $x_{s_0}$ that generates the lowest $p$-value below a specified level $\alpha$. In case of all candidate variables that do not produce a significant split, the root node is declared as terminal and the global constant model is selected as the best model. Otherwise, two children nodes are generated to compose the first depth of the tree.

2. Conditional to the choice of $s_0$, estimate the vector of parameters $\psi = (\gamma_0, c_0, \beta_1, \beta_2)'$ by concentrated least squares.

4.2.2. Modeling cycle from the first depth

After the tree has started to grow from the root node, the first depth is created and the cycle continues by testing for the adequacy of splitting one between the two children nodes. The null hypothesis in this test concerns the conditional linear model and the alternative brings the inclusion of a nonlinear term that is responsible for splitting the node. From now on, besides selecting a splitting variable, we shall also select which one between the two created nodes shall be split at the first place.

1. For each combination of splitting variable index in $S = \{1, 2, \ldots, m\}$ and node number in $D_1 = \{1, 2\}$, apply the LM-type test and select the indexes $j_1 \in D_1$ and $s_{j_1} \in S$ that generates the lowest $p$-value below a pre-specified significance level. If there is no significant split, the tree growing process stops.

2. Estimate the parameters of the model.

4.2.3. Modeling cycle from the $k$th depth

The execution of the algorithm in a general depth $k$ is straightforward.

1. Apply the LM test to all combinations of splitting variables indexes and nodes in the set $D_k$ which contains all numbers of children nodes that compose the $k$th depth. Note that $D_k \subseteq \{2^k - 1, 2^k, \ldots, 2^k + 1 - 2\}$.

2. Select $j_1 \in D_k$ and $s_{j_k} \in S$ by the rank of significant $p$-values obtained through the LM-type test.

3. Estimate the parameters of the model.

The whole modeling cycle ends when a determined depth do not produce children nodes.

4.3. Sequential tests

To achieve the final tree model, we perform a sequence of $n$ correlated LM-type tests of hypothesis in which $n$ is a random variable. Due to multiplicity from repeated significance testing, we have to control the overall type I error under the risk of an overstatement of the significance of the results (more splits are reported to be significant than it should be). To remedy this situation, we adopt the following procedure. For the $n$th test in the sequence, if it is performed in the $d$th depth the significance level is $\alpha(d, n) = \alpha/n^d$. In the root node ($d = 0$) and we apply the first test ($n = 1$) for splitting the node at a significance level $\alpha$, if the null is rejected than the second ($n = 2$) test is applied in the first depth ($d = 1$) and the significance level is $\alpha/2$. By forcing the test to be more rigorous in deeper depths, we create a procedure that diminishes the importance of using post-pruning techniques. There are several alternatives to control the overall size of the sequence of tests: Hochberg (1988), Benjamini and Hochberg (1995, 1997), Benjamini and Yekutieli (2000, 2001), and Benjamini and Liu (1999). However, by our experiments, our simple methodology works well and the comparison between different techniques to reduce the nominal size of each test is beyond the scope of the paper.
5. Categorical data

In principle, the previous developments do not take into account the case where some of the variables are categorical. However, the extension to include categorical data is straightforward. The main idea is to replace the constant model in each terminal node by a linear regression on a constant and a set of dummy variables representing the categorical data.

Let $\mathbf{x}_t = (\mathbf{z}_t^\prime, \mathbf{w}_t^\prime)^\prime$, where $\mathbf{z}_t$ is a vector of categorical variables and $\mathbf{w}_t$ is a vector of continuous variables. Let $\mathbf{D}_t(\mathbf{z}_t)$ be a vector of dummy variables representing the categorical vector $\mathbf{z}_t$. In that case model (7) may be rewritten as

$$y_t = H(\mathbf{x}_t; \psi) + \epsilon_t = \sum_{k=1}^{K} \beta_{K+i-1}^\prime \mathbf{D}_t(\mathbf{z}_t) B_k(\mathbf{w}_t; \theta_k) + \epsilon_t. \quad (23)$$

6. Monte Carlo experiment

In this section study the small sample properties of the nonlinear least squares estimators under correct specification of the STR-tree model and investigate the performance of three different tree-growing algorithms:

CART: We use the most traditional CART tree growing strategy. This consists of growing the tree using as a stopping rule the minimum of five observations per terminal node, and then prune the tree using the 1-SE rule with errors estimates obtained by 10-fold cross validation.

STR-tree/LM: This strategy uses the LM test to select the node and splitting variable. This specification strategy does not need pruning and the control of the overall error is done by the reducing the test size during the tree growing.

STR-tree/CV: We carry at each node a 10-fold cross-validation experiment to select the splitting variable that minimizes the overall mean square of errors (MSE) evaluated out-of-sample.

We simulate two tree architectures which are illustrated in Fig. 2, with different combinations of smoothness parameters. Thus, five models are simulated for Architecture I which contains three terminal nodes and three models are simulated for Architecture II which has four terminal nodes. Basically, we consider three types of splits (see Table 1): very smooth ($\gamma_j = 0.5$), moderate sharp ($\gamma_j = 5$), and sharp ($\gamma_j = \infty$). The sharp splits are used to evaluate the robustness of the STR-tree model when the true specification is a regression-tree with hard thresholds. We also mix types of splits.

Model 1.1, for example, is obtained from two consecutive smooth splits and Model 1.4 brings a smooth split at the root node, followed by a moderate sharp split.

We simulate 1000 replications for each model with sample sizes $T = 150$ and 500. As the main concern is about the effects of the slope parameter, there is not much variation in the choice of the constants within the nodes. Three uncorrelated and normally distributed predictor variables are used as candidates to be the splitting variables: $x_1 \sim N(10, 2.56); x_2 \sim N(90, 9);$ and $x_3 \sim N(25, 4)$. The error term is defined as $\varepsilon_i \sim N(0, 1)$. Since the slope parameter is not scale-free, we standardize the argument of the logistic function, dividing it by the standard deviation of the splitting variable. The other parameters are fixed according to Table 2. In the simulations concerning parameter estimation we do not consider the cases where $\gamma \sim \infty$.

As shown in Table 2, the location parameters are chosen strategically at median points for simulations under Architecture II. The aim is to provide a maximum amount of information within the created nodes. The only concern related to the choice of the constants within the nodes is to yield different local models.

The difference among models for Architecture I can be seen in Fig. 3, which shows the response surface for each one of the simulated trees. When all splits are moderate sharp such as in model 1.2, the surface looks like a bivariate histogram. On the other hand, a sequence of extremely smooth splits (Model 1.1) produces a relationship between the response and regressors that is almost linear.

6.1. Parameter estimation

In this section, we discuss the empirical results obtained with the use of the NLSE in the simulated models. The results are described through descriptive statistics such as the sample mean. Two measures are chosen to evaluate the variability of the estimates; the sample standard deviation and, as a more robust alternative, the median absolute deviation around the median ($\text{MAD}$):

$$\text{MAD}(\hat{\psi}) = \text{median}(|\hat{\psi} - \text{median}(\hat{\psi})|) .$$

Estimation of the slope parameter $\gamma$ results in outliers and extreme values for some replications, hence the sample mean of the estimates is strongly affected by them. It is clear in Tables 3 and 4 that the parameter $\gamma$ is strongly overestimated when $T = 150$. In these cases, the median seems to be a more robust measure of central tendency. Such problem does not occur with the location parameter, whose sample mean and median are close to the true value. Nevertheless, the variability of the location parameter estimator increases whenever there is a smooth split. As a consequence, the estimates of the parameters within the nodes are also affected, mainly in small samples. Thus, as it happened with Model 1.3, the sample mean and median for the local model estimates deviate from the population values. In general, the estimates, except for the smoothness parameter, are more precise in trees simulated with sharp splits. When mixing different types of splits, the results pointed out that a smooth split followed by a sharp split produces better results. In this situation, there are more observations left to be modeled after the first split. Finally, an important aspect of the simulation study is the indication that the NLS estimates converged, as expected, to the true value of the parameter whenever the sample size increases.

6.2. Tree architecture specification by different algorithms

We show in Tables 5 and 6, the performance of the three algorithms to identify the simulated STR-tree models.

When all partitions involve only moderate sharp splits, the STR-tree models yield more than 95% of correct specifications, independently of the simulated architecture. When $T = 150$, the sequence of LM tests produced significantly
better results than 10-fold cross-validation. For $T = 500$ the performance of both are comparable, being the LM test slightly better. On the other hand, all strategies faced more trouble to specify correctly trees which were grown from very smooth splits. A very smooth split followed by a sharp one increased the number of misspecifications. However, the STR-tree model specified by the LM test outperforms its competitors in most of the cases. The decision to generate trees with a highly smooth transition function at the first node turned the specification task very difficult for all algorithms, even so the STR-tree/LM could perform quite satisfactorily in large samples. The main problem for this algorithm occurred in the situation involving a very smooth split at the root node followed by a sharp split in the subsequent node. It could specify neither the tree architecture nor the splitting variables. Whenever the CART algorithm is submitted to specify smooth trees, it tends to create less nodes than expected. In the opposite situation where the splits are moderate sharp, even the post-pruning procedure was not able to avoid overfitting. The strategy to use a 10-fold cross-validation experiment during the specification seems to produce results in the STR-tree algorithm which are similar to CART ones. Although the overfitting is not so dramatic as in the CART case, when the splits are moderate sharp, the algorithm tended to create, mainly in small samples, trees which are larger than expected. With large samples and moderate sharp splits, the specification performance is comparable to the one done by the sequence of LM-type tests, but the computational burden is considerably high.

Finally, when the true model is a regression-tree with hard splits, the CART algorithm, as expected, performs very well. However, the STR-tree model specified with the LM strategy is also very accurate, correctly selecting the true architecture in almost all replications. On the other hand, the 10-fold cross-validation is not a viable alternative to build

STR-tree models when the splits are hard. Surprisingly, when the splits change from moderate sharp ($\gamma_i = 5$) to sharp ($\gamma_i = \infty$), the performance of the CART algorithm improves dramatically.

6.3. Out-of-sample predictions

In order to evaluate the out-of-sample performance of the STR-tree model we conduct the following experiment. We simulated 1000 replications with 750 observations of the following models:

- Model 1: Equation (66) in Friedman (1991)

$$y_i = \frac{40 \times \exp[8((x_{1i} - 0.5)^2 + (x_{2i} - 0.5)^2)]}{\exp[8((x_{1i} - 0.2)^2 + (x_{2i} - 0.7)^2)] + \exp[8((x_{1i} - 0.7)^2 + (x_{2i} - 0.2)^2)]} + \epsilon_i,$$

where $\epsilon_i$ is drawn from a standard normal distribution and $x_{1i}$ and $x_{2i}$ are drawn from a uniform distribution in the unit square.

where \( f(z) = [1 + \exp(-z)]^{-1} \), \( x_{1i} \) and \( x_{2i} \) are drawn from a uniform distribution in the unit square, \( x_{3i} \) is drawn from a normal distribution with mean 5 and standard deviation 4, and \( \varepsilon_i \) is normally distributed with zero mean and unit variance.

• Model 3: Example 1 in Fan and Zhang (1999)

\[ y_i = \sin(60x_{1i})x_{2i} + 4x_{1i}(1 - x_{1i})x_{3i} + \varepsilon_i, \]

where \( x_{1i} \) is follows a uniform distribution and \( x_{2i} \) and \( x_{3i} \) are normally distributed with zero mean, unit variance, and correlation coefficient \( 2^{-1/2} \).

• Model 4: Example 3 in Fan and Zhang (1999)

\[ y_i = \sin[8\pi(x_{1i} - 0.5)]x_{2i} + \{3.5[\exp(-4x_{1i} - 1)^2] + \exp(-4x_{1i} - 3)^2\} - 1.4|x_{3i} + \varepsilon_i. \]

All the variables are defined as in Model 3.

For each replication we fit four different models using 500 observations: a STR-tree model specified with the sequence of LM tests; a regression-tree estimated with CART; a neural network with 10 hidden neurons estimated with Bayesian regularization (MacKay, 1992); and MARS (Friedman, 1991). For each estimated model, we generate out-of-sample predictions for the remaining 250 observations and we also compute the mean squared errors (MSE). Table 7 reports the median, the MAD, the maximum, and the minimum of the MSEs over 1000 replications.

Analyzing the results in Table 7, the STR-tree model performs quite well. In three out of four cases, the STR-tree model delivers the lowest median of the out-of-sample MSEs. Only for Model 1, the STR-tree specification is worse than the neural network, but it is significantly better than the CART and the MARS alternatives.

7. Real examples

In this section we apply the STR-tree model to several data sets.

• Boston Housing: Housing values in 506 census tracts of Boston. This is the same data set used in Breiman et al. (1984).

• Cpus data: The Cpus data is discussed in Venables and Ripley (2002). The goal is to explain the performance of 209 different CPUs by some hardware characteristics.

• Car sales in USA in 1993: The data were taken from MASS library in R and describe the prices and other 25 variables of 93 new cars models.

• Auto imports: This data set was taken from Ward’s 1985 Automotive Yearbook and consists of 195 prices of cars followed by some features such as: fuel consumption, length, width, engine size, among others.

• Abalone data: This is a data set originated from Biology and the objective is to predict the age of an abalone from a set of physical measurements. There are 4177 cases and seven continuous predictors. The source is the UCI repository.

</table>

- MPG data: The data set concerns city-cycle fuel consumption in miles per gallon, to be predicted in terms of five continuous attributes. There are 398 observations.

By choosing the data sets above we consider both small and large samples. In some cases the regressors are highly correlated. In all cases we select only the continuous variables. To get an honest picture of the performance reached by all models, we conduct an out-of-sample evaluation by repeating 10 times a 10-fold cross-validation experiment. In each of the 10 replications we randomly split the data in 10 parts, using nine parts to estimate the model and one part to evaluate the out-of-sample performance. We repeat this leaving each one of the 10 parts for out-of-sample evaluation. This means that for each of the 10 replication, we have 10 sets of mean squared errors with $N/10$ observations in each set. $N$ is the number of observations in the data set. As we repeat the experiment 10 times, in the end we have $10N$ out-of-sample squared errors, reflecting different combinations of estimation (in-sample training) and testing (out-of-sample evaluation) sub-samples. Table 8 reports the median, the MAD, the maximum, and the minimum of the squared errors.

We compared the performance of the following models: CART, MARS, STR-tree specified with the sequence of LM tests (STR-tree/LM), STR-tree specified with 10-fold cross-validation (STR-tree/CV), and a Neural Network with 10 hidden units estimated with Bayesian regularization. We also consider three possible combination models using a simple averaging scheme. The combinations are: MARS and CART, MARS and STR-tree/LM, and CART and STR-tree/LM.

When compared to CART, the STR-tree/LM model has a better performance in five out of six cases. The only exception is the Auto Imports data set, where CART performs slightly better. The STR-tree/LM model outperforms the NN alternative in three out of six cases (CPUS, Car sales, Import). In the MPG data set the STR-tree/LM is worse than the NN model, but the STR-tree/CV has a lower median of the MSEs. Comparing with MARS, the STR-tree/LM model has a superior behavior in two out of six cases (Car sales and Import). The STR-tree/CV is better than the MARS in the
MPG data set. With respect to the Boston data set, the STR-tree/CV, NN, and CART models have similar performance. When the CPUS data set is considered, the out-of-sample behavior of the STR-tree/LM, NN, and CART specifications are similar. Finally, the simple averaging of the STR-tree/LM and MARS models leads to the best alternatives in four out of six cases. The two exceptions are the Abalone and the Import data sets. In the former MARS is the best model while in the latter the combination of MARS and CART turns to be the best alternative.

8. Conclusions

In this paper, we proposed a model that combines regression trees and smooth transition regressions. The model is called the Smooth Transition Regression Tree (STR-tree). The resulting model can be analyzed as a smooth transition regression with multiple regimes. A detailed analysis of the asymptotic properties of the parameter estimates was presented and a model building procedure, based on a sequence of Lagrange multiplier (LM) tests, was developed. An alternative specification strategy based on a 10-fold cross-validation was discussed and a Monte Carlo experiment was carried out to evaluate the performance of the proposed methodology. The STR-tree model outperforms CART when the correct selection of the architecture of simulated trees is considered. Furthermore, the LM test seems to be a promising alternative to 10-fold cross-validation. In addition, the proposed estimation algorithm works properly in small samples. When put into proof with real data sets, the STR-tree model outperformed CART and was highly competitive against other nonlinear alternatives.

Acknowledgments

This work is partly supported by CNPq and FAPERJ. We wish to thank two anonymous referees for helpful comments, and Timo Teräsvirta and Dick van Dijk for valuable discussions.

Appendix A. Proofs

A.1. Proof of Theorem 1

Lemma 2 of Jennrich (1969) shows that the conditions (1)–(3) in Theorem 1 are enough to guarantee the existence (and measurability) of the NLSE.

Condition (3) in Theorem 1 is satisfied by Assumption 2. It is easy to prove that \( H(x_t; \psi) \) is continuous w.r.t. the parameter vector \( \psi \). This follows from the fact that, for each value of \( x_t \), \( B_k(x_t; \theta_k) \) depends continuously on \( \theta_k \), \( k = 1, \ldots, K \). Similarly, \( H(x_t, \psi) \) is continuous in \( x_t \), and therefore measurable, for each fixed value of \( \psi \). Thus (1) and (2) are satisfied.

A.2. Proof of Theorem 2

Following Jennrich (1969) and Amemiya (1983), \( \psi \xrightarrow{a.s.} \psi^* \) if the following conditions hold: (1) the parameter space \( \Psi \) is compact; (2) \( Q_T(\psi) \) is continuous in \( \psi \in \Psi \) for all \( x_t \in \mathbb{X} \) and for all \( y_t \in \mathbb{R} \) and \( Q_T(\psi) \) is a measurable function of \( x_t \) and \( y_t \) for all \( \psi \in \Psi \); and (3) \( Q_T(\psi) \xrightarrow{a.s.} Q(\psi) = \mathbb{E}(y_t - H(x_t; \psi))^2 \).

Condition (1) is satisfied by Assumption 3. Using the results of Theorem 2, Condition (2) is satisfied. To check if Condition (3) is satisfied we will follow the steps in Amemiya (1983). From (7) and (8) we get

\[
Q_T(\psi) = \frac{1}{T} \sum_{t=1}^{T} \varepsilon_t^2 + \frac{2}{T} \sum_{t=1}^{T} [H(x_t; \psi^*) - H(x_t; \psi)] \varepsilon_t + \frac{1}{T} \sum_{t=1}^{T} [H(x_t; \psi^*) - H(x_t; \psi)]^2
\]

\[
\equiv A_1 + A_2 + A_3.
\]

It is straightforward to see that \( A_1 \xrightarrow{a.s.} \sigma^2 \) by the Strong Law of Large Numbers. Under Assumption 3 and the continuity of \( H(x_t; \psi) \) on \( \Psi \), Theorem 15 in Jennrich (1969) implies that \( A_2 \xrightarrow{a.s.} 0 \).

Now it is sufficient to show that the following condition is satisfied.
(3') \( (1/T) \sum_{t=1}^{T} H(x_t; \psi_1) H(x_t; \psi_2) \) converges uniformly in \( \psi_1, \psi_2 \in \Psi \).

Assumption 1, and the fact that \( H(x_t; \psi) \preceq \tilde{\beta} \), where \( \tilde{\beta} = \sum_{k=1}^{K} |\beta_{k+K-1}| < \infty \), Condition (3') is satisfied; see Jennrich (1969). Finally we have to show the following condition is satisfied.

\[
\lim_{T \to \infty} (1/T) \sum_{t=1}^{T} [H(x_t; \psi^*) - H(x_t; \psi)] \neq 0 \text{ if } \psi \neq \psi^*.
\]

The above condition is satisfied by Assumption 4, which guarantees that the STR-tree model is globally identified.

### A.3. Proof of Theorem 3

To prove the asymptotically normality of the NLSE we need the following conditions in addition to the ones stated in the proof of Theorem 2.

1. The true parameter vector \( \psi^* \) is interior to \( \Psi \).
2. The score vector satisfies
\[
\frac{1}{\sqrt{T}} \frac{\partial Q_T(\psi^*)}{\partial \psi} \xrightarrow{d} N(0, \mathbf{C}(\psi^*)),
\]

where
\[
\mathbf{C}(\psi^*) = \lim_{T \to \infty} \mathbf{E} \left[ \frac{1}{T} \frac{\partial Q_T(\psi^*)}{\partial \psi} \frac{\partial Q_T(\psi^*)}{\partial \psi'} \right].
\]

3. The Hessian
\[
\frac{1}{T} \frac{\partial^2 Q_T(\psi^*)}{\partial \psi \partial \psi'} \xrightarrow{p} \mathbf{D}(\psi^*),
\]

where
\[
\mathbf{D}(\psi^*) = \lim_{T \to \infty} \mathbf{E} \left[ \frac{1}{T} \frac{\partial^2 Q_T(\psi^*)}{\partial \psi' \partial \psi} \right].
\]

Assumption 3 guarantees that Condition (4) is satisfied. In order to check if Condition (5) is satisfied we have to analyze the behavior of

\[
\frac{1}{\sqrt{T}} \frac{\partial Q_T(\psi^*)}{\partial \psi'} = \frac{2}{\sqrt{T}} \sum_{t=1}^{T} \epsilon_t \frac{\partial H(x_t; \psi^*)}{\partial \psi'}.
\]

As, by Assumption 2, \( \epsilon_t \sim N(0, \sigma^2) \), we have to show that

\[
\lim_{T \to \infty} \frac{1}{T} \sum_{t=1}^{T} \frac{\partial H(x_t; \psi^*)}{\partial \psi} \frac{\partial H(x_t; \psi^*)}{\partial \psi'} \equiv \mathbf{H}
\]

exists and is non-singular; see Amemiya (1983). First, note that

\[
\frac{\partial H(x_t; \psi^*)}{\partial \psi' = \left( B_1(x_t; \theta_1^*), \ldots, B_K(x_t; \theta_K^*), \beta_{k-1}^* \frac{\partial B_1(x_t; \theta_1^*)}{\partial \theta_1'}, \ldots, \beta_{2K-2}^* \frac{\partial B_K(x_t; \theta_K^*)}{\partial \theta_1'} \right)'.
\]

By the definition of the STR-tree model, \( B_k(x_t; \theta_k^*) \leq 1 \), \( k = 1, \ldots, K \). Furthermore \( B_k(x_t; \theta_k^*) \), \( k = 1, \ldots, K \), is the product of at most \( d \) (depth of the STR-tree model) logistic functions of \( x_t \), such that

\[
\frac{\partial B_k(x_t; \theta_k^*)}{\partial \theta_k'} \leq a(x_t; \theta_k^*) + \sum_{j=1}^{d} c_j(x_t; \theta_k^*) |x_{s_j-1}|, \quad k = 1, \ldots, K,
\]

(A.1)
where \( a(x_t; \theta_k^*) \leq M < \infty \) and \( c_j(x_t; \theta_k^*) \leq 1 \), \( j = 1, \ldots, d \). Then, Assumption 2, the unique identification of \( \psi^* \) (Assumption 5), and (A.1) guarantee that Condition (5) is satisfied.

To verify Condition (6) we have to show that:

\[
(6') \quad \text{The sum}
\frac{1}{T} \sum_{t=1}^{T} \frac{\partial H(x_t; \psi)}{\partial \psi} \frac{\partial H(x_t; \psi')}{\partial \psi'}
\]

converges uniformly in \( \psi \) in an open neighborhood of \( \psi^* \).

\[
(6'') \quad \text{The sum}
\frac{1}{T} \sum_{t=1}^{T} \left[ \frac{\partial^2 H(x_t; \psi)}{\partial \psi \partial \psi'} \right]^2
\]

converges uniformly in \( \psi \) in an open neighborhood of \( \psi^* \).

First, \( H(x_t; \psi^*) \) is twice continuously differentiable and following the same reasoning as before

\[
\frac{\partial^2 B_k(x_t; \theta_k^*)}{\partial \theta_k \partial \theta_k^*} \leq u(x_t; \theta_k^*) + \sum_{i=1}^{d} \sum_{j=1}^{d} v_{ij}(x_t; \theta_k^*) |x_{s_1-1}| |x_{s_2-1}|, \quad k = 1, \ldots, K,
\]

(A.2)

where \( u(x_t; \theta_k^*) \leq M' < \infty \) and \( v_{ij}(x_t; \theta_k^*) \leq 1 \), \( j = 1, \ldots, d \). Then Condition (6'') is satisfied.

A.4. Proof of Theorem 4

This is a standard result in regression analysis and the proof will be thus omitted.
